Abstract

Background: Athletes tend to have better visuomotor performance than do sedentary individuals. However, several basic visual-function and perceptual parameters remain unexplored to date. In this study, we investigate whether differences exist in visual function, performance, and processing between basketball players and individuals without a sport-involvement background.

Methods: A total of 33 healthy men with no visual impairment or pathology were divided into 2 groups based on their involvement in sport (semi-professional basketball players and sedentary individuals). We tested their baseline heart rate variability (HRV) in the resting position apart from subjective questionnaires to determine their physical fitness level, and checked their visual function, performance, and processing through an extended battery of optometric tests.

Results: The 2 groups differed in resting HRV parameters (p < 0.001), which confirms their dissimilarities in regular time practicing sports per week. The basketball players showed a closer breakpoint and recovery near point of convergence, higher fusional-vergence rate, better discriminability halos, and eye-hand coordination (all p < 0.05).

Conclusion: These results evidence that athletes, basketball players in this case, exhibit better performance in several visual abilities in comparison with a group of individuals without sporting backgrounds, which suggests an improvement due to the systematic involvement of those skills during basketball practice.

1. Introduction

Athletes need to gather a great amount of information, mainly visual, swiftly from the environment in order to execute appropriate motor tasks.1 There is evidence that athletes develop peculiar mechanisms of occipital neural synchronization during visuospatial demands, showing better visuomotor performance compared to non-athletes.2 Previous studies tend to indicate that athletes present better visual skills than do sedentary individuals but this issue is far from being settled.3 Several studies questioned whether visual skills in athletes are innate or whether they are improved with systematic sport practice and sports vision training programs help to improve certain visual abilities, while the innate contributions seem to be insignificant.5,6

Previous investigation suggests that particular sets of visual skills are sport-dependent because each discipline has differing visual needs and demands.7 The visual information during basketball, as a dynamic sport, comes from the position of the ball and player. Thus, basic visual function based on good optical quality, oculomotor coordination, binocular, and accommodative function or stereopsis are crucial to success in ball games, and particularly in basketball.8 In addition, a player’s performance depends on cognitive capabilities and the visuomotor reaction times.9

Nevertheless, it has not been clarified whether athletes’ superiority is due to basic visual function or perceptual and cognitive skills.10 An increasing body of knowledge supports a multidimensional approach, considering visual, perceptual, and...
cognitive factors to characterize expertise. Although some studies have concluded that athletes possess better visual function than do sedentary individuals, few investigations have used an extended optometric battery of tests in a specific sport discipline, and thus no solid conclusions have been drawn to date. For example, differences between professional volleyball players and a control group have been reported for saccadic eye movements and facility of ocular accommodation, as well as a better near stereaoacity in young baseball and softball players in comparison to non-ball players. By contrast, Paulus et al. found that stereopsis in soccer players was similar to that of individuals without a soccer background. On the other hand, visual information processing also plays a fundamental role in sport performance, which permits a precise decision-making process in a certain amount of time. Several studies have shown that athletes have an improved peripheral awareness, ability to track a moving target, and a different strategy in the treatment of visual information, among other advantages, than do non-athletes or less experienced players. Specifically, in a recent study, Mangine et al. found a relationship between faster visual-tracking speed and better basketball-specific performance in National Basketball Association (NBA) players.

Considering the previous literature and the ongoing debate concerning the differences in visual function and perceptual abilities between athletes and the sedentary population, in the present study we investigate the basic visual function and perceptual visual skills in a specific sport discipline, basketball in our case, in order to provide more knowledge in this regard. Therefore, we tested several parameters related to the basic visual function such as accommodative response, near point of convergence, near and far fusional vergences, and near and far stereooacity. Regarding perceptual abilities, we also assessed visual performance by visual-discrimination capacity and visual-information processing by visual-reaction time and eye-hand coordination.

Additionally, exercise practice has demonstrated to improve the autonomic balance with an increase in parasympathetic and a decrease in sympathetic control of heart rate (HR). Heart rate variability (HRV) analysis with the time and frequency domains permits assess to the state of the autonomic nervous system, which indirectly reflects fitness level. To check the differences in physical exercise involvement between athletes and individuals without a sport background, we measured HRV at rest and compiled subjective report data. We hypothesized that inherent visual involvement during systemic basketball practice can improve both the basic visual function and the main perceptual visual parameters involved. The answer to our research question can have theoretical and practical consequences for basketball performance and training protocols.

2. Materials and methods

2.1. Participants and ethical approval

The study included a total of 33 male university students, of which 18 belonged to different basketball teams in a regional league and 15 had no history of sporting activity (age: 23.28 ± 2.37 years, and 22.27 ± 2.09 years, mean ± SD, respectively; Table 1). Participants were asked for the type of sport activities they were engaged in, apart from basketball, and the amount of time dedicated to each sport discipline. From the basketball group, 15 out of 18 reported to practice strength training in addition to the basketball sessions, and the other 3 were only engaged in basketball. All basketball players had been playing at competitive levels for at least 7 years (10.24 ± 2.27 years). Of the sedentary participants, 8 individuals reported to occasionally practice team sports and the rest of them (7 participants) were not involved in any physical activity. This study was conducted abiding by the Code of Ethics of the World Medical Association (Declaration of Helsinki) and permission was provided by the Institutional Review Board of University of Granada. All participants gave written informed consent prior to the study.

Admission criteria included (a) being healthy; (b) participating in ≥ 6 h of moderate exercise per week for the athletes group and ≤ 1 h of exercise per week for the non-athletes group; (c) not presenting any ocular pathology; (d) not taking any medication; (e) presenting static monocular (in both eyes) and binocular visual acuity (VA) ≤ 0 Logarithm of the minimum angle of resolution (logMAR) (≥ 20/20); (f) having a corrected refractive error ≤ ±3.5 D for myopia and hyperopia, ≤ ±1.5 D of astigmatism, and being contact lenses wearers; and (g) scoring less than 25 on the Conlon Survey, which assesses visual discomfort, and less than 21 at the Convergence Insufficiency Symptom Survey (CISS) (Table 1). All participants were instructed to avoid alcohol consumption and vigorous exercise 24 h before the experimental session, to sleep for at least 7 h, not to consume caffeinated beverages or other stimulants in the 3 h prior to testing, and to follow the regular diet but not to eat 2 h prior to testing.

2.2. Test procedures and apparatus

2.2.1. HRV measure and analysis

To ensure physical involvement differences, we measured HRV. A number of studies have concluded that endurance training enhances vagal tone in athletes, which may contribute

in part to lower the resting HR. Thus, before the visual examination, the participant was asked to lie in a supine position in a quiet room for 6 min. The HR was monitored by using a Polar RS800CX wrist device (Polar Electro Oy., Kempele, Finland), set to measure both the HR and HRV. The time series of HRV was taken from the electrocardiogram, which identified the occurrence of each R wave (belonging to the QRS complex) and calculated the time lapse between 2 consecutive R waves. Subsequently, the data were transferred to the Polar ProTrainer Software (Polar Electro Oy.) and each downloaded R-R interval (inter-beat R wave to R wave) file was then further analyzed using the Kubios HRV Analysis Software 2.0 (The Biomedical Signal and Medical Imaging Analysis Group, Department of Applied Physics, University of Kuopio, Kuopio, Finland). R-R intervals that differed more than 25% from the previous and subsequent R-R intervals were excluded. Those removed R-R intervals were replaced by conventional spline interpolation so that the length of the data did not change. In this study, the parameters used to analyze HRV within the time domain were the mean R-R interval (RRi), and the root-mean-square difference of successive normal R-R intervals (rMSSD), and within the frequency domain were the low-frequency (LF) and high-frequency (HF) components in normalized units (nu), which are established between 0.04–0.15 Hz and 0.15–0.40 Hz, respectively.

2.2.2. Ocular and visual examination

Ocular parameters related to ocular refraction; accommodative and binocular function; visual performance; and visual information processing were examined. All tests were conducted under photopic illumination conditions (152.4 ± 2.45 lux), with the exception of visual-discrimination in scotopic illumination conditions (~0 lux), which were quantified in the corneal plane with an illuminance meter T-10 (Konica Minolta, Inc., Tokyo, Japan).

2.2.3. Ocular refraction

Monocular and binocular VA was determined using a computerized monitor with the logarithmic charts test employing the Bailey-Lovie design (POLA VistaVision, DMD Med Tech SRL, Torino, Italy) at a distance of 5 m. Ocular refraction consisted of an objective refraction with non-cycloplegic retinoscopy while the participant maintained a fixed gaze on a distant non-accommodative target, and finally each participant underwent a full monocular and binocular subjective refraction, using an endpoint criterion of maximum plus consistent with best vision.

2.2.4. Accommodation, binocular, and oculomotor parameters

All tests were conducted with the best correction following the recommendations given by Scheiman and Wick. The accommodative response, measured by the monocular estimate method (MEM) retinoscopy, was carried out by very briefly interposing, in front of 1 eye at a time, convergent or divergent lenses until neutralizing the reflex found in the horizontal meridian, while the participant read a test close-up with 0.18 logMAR (20/30) letters.

The near point of convergence was evaluated by the push-up technique using an accommodative target. A 0.18 logMAR (20/30) single letter on the fixation stick was used as the target. The target was moved closer until the participant experienced constant diplopia on the stick (breakpoint). Then the participant moved the stick away from the eye until single vision was restored (recovery point).

Near and distance negative and positive vergence amplitude were measured. The negative fusional vergence was measured first to avoid affecting the vergence-recovery value because of excessive stimulation of convergence. A gradually increasing prism bar was introduced in the dominant eye while the participant fixed the gaze on a column of the Snellen optotype, corresponding to the highest VA at 40 cm and 6 m fixation, respectively. When the prism caused the participant to experience double vision, the amount of prism (breakpoint) was recorded. The prism power was then reduced until the double images could be fused again (recovery point).

Static far stereo acuity was tested using the Stereo D6/D8 (POLA VistaVision, DMD Med Tech SRL, Torino, Italy) at 5 m away using a polarizing viewer. This test presents a range from a maximum of 300 s of arc to a minimum of 10 s of arc and only 1 circle from 5 possible choices had crossed disparity. The participant was asked to identify which circle seemed to be at a different distance with respect to the other 2 (at near) or 4 (at distance). Static near stereo acuity was measured using the Randot Stereotest Circles (Stereo Optical Company, Chicago, IL, USA) at a distance of 40 cm. Within each of 10 targets, there were 3 circles. This test presents a range from a maximum of 400 s of arc to a minimum of 20 s of arc. The level of stereoacuity was recorded as the last series of targets correctly answered.

To test facility of accommodation, the Hart chart was read under binocular conditions. This procedure presents blur and vergence-related visual feedback and function in an interactive manner. Participants were instructed to alternatively read 1 letter from the distance Hart chart (5 m) in primary position, and then shift their focus to the near Hart chart (40 cm) placed 30° inferiorly, and so forth across the lines of letters as rapidly as possible. The number of cycles completed in 60 s were determined, as well as the number of errors made.

2.2.5. Visual performance

We evaluated the visual-discrimination capacity, quantifying the visual disturbances perceived by the participant using a visual test conducted by the software Halo Version1.0 (freeware software, University of Granada, Granada, Spain). The participant’s task consisted of detecting luminous peripheral stimuli around a central high-luminance stimulus over a dark background. All the stimuli were achromatic. The distance from the observer to the test monitor (1280 × 1024 LCD screen) was 2.5 m and the test was performed binocularly. The size of the stimulus was 39 pixels for the radius of the central stimulus and 1 pixel for the peripheral one, subtending 0.61 and 0.02 degree, respectively, from the observer’s position. The monitor showed 72 peripheral stimuli around the central one, distributed along 18 semi-axes. Each of the 72 stimuli was presented twice. After
a 3 min period of adaption to the darkness of the monitor background, there was 1 min adaptation to the main stimulus, and then the participant was randomly presented with peripheral stimuli around the central stimulus. On detecting peripheral spots, the participant pressed a button on the mouse to store this information for subsequent treatment and calculation of the visual disturbance index (VDI) after the test was concluded. The VDI takes values from 0 to 1. A greater value indicates a greater contribution of visual disturbances, such as glare or visual halos around the luminous stimuli, and therefore poorer discrimination capacity.

2.2.6. Visual-information processing

The Wayne Saccadic fixator (Wayne Engineering, Skokie, IL, USA) was used for evaluating visual-reaction time. This apparatus consists of a 29-inch square panel containing 33 red lights switches. A computer chip generates a variety of patterns of light to which an individual responds by pushing the illuminated switch to extinguish the light. A great variety of display patterns, speed, and situations can be programmed. The Sports Vision Release/Locate Reaction Time program, used to test visual-reaction time, was performed 3 times after familiarization. The test instructions consisted of pressing the start (reset) button, holding button down until a signal is heard (liberalization time), releasing the button, and pressing the illuminated light (button) on the saccadic fixator (localization time). Just 1 light was used and appeared in a random position each time. Two scores were given to each trial, for the time of liberalization (milliseconds) and location.29,30

To test eye–hand coordination, we used a standardized test developed by Dr. Jack Gardner with the Wayne Saccadic Fixator, which jointly takes into account the proaction (time period in which each light stays lit until the button is pressed) and reaction times (preset amount of time in which each light stays lit before automatically switching to another light regardless of whether the button is pressed) for accurate and repeatable rapid testing. The lights start moving automatically at the preset speed (60 light/min). For each correct response, the speed increases. At the end of the preset time (30 s), the display shows the number of correct responses, the average speed, and the final speed in units of light/min. The score was the product of the number of lights scored and the final speed of presentation of the lights.29

Three measurements were taken in MEM, near point of convergence (break point and recovery point) and visual-reaction time, and the mean value was used. When both eyes had to be independently measured, the order of the first eye to store this information for subsequent treatment and calculation of the visual disturbance index (VDI) after the test was concluded. The VDI takes values from 0 to 1. A greater value indicates a greater contribution of visual disturbances, such as glare or visual halos around the luminous stimuli, and therefore poorer discrimination capacity.

2.3. Statistical analysis

All variables tested were subjected to the Shapiro-Wilk test, and showed a normal Gaussian distribution. Thus, to analyze the differences on visual function between basketball players and sedentary participants, a separate t test was performed for independent samples with each variable tested. We used the Bonferroni correction for multiple comparison. A value of 0.05 was adopted to determine significance.

3. Results

3.1. Sample manipulation check

The t test for independent samples showed significant differences between basketball players and sedentary participants in the HR (beat/min) \( t_{31} = -7.07, p < 0.001 \), RRi (ms) \( t_{31} = 7.09, p < 0.001 \), rMSSD (ms) \( t_{31} = 5.14, p < 0.001 \), LF (nu) \( t_{31} = -5.28, p < 0.001 \), and HF (nu) \( t_{31} = 5.27, p < 0.001 \) (Table 2). Also, a t test for independent samples was performed for hours per week of exercise \( t_{31} = 21.179, p < 0.001 \), and for hours per week of basketball practice \( t_{31} = 39.57, p < 0.001 \) reported by participants. Hence, the 2 samples had different fitness levels.

3.2. Visual parameters

Table 3 presents mean values ± SD and significance for all parameters tested in this study.

The analysis for fusional vergence showed that athletes had higher far-positive fusional vergence range \( t_{31} = 2.69, p = 0.011 \) for the breakpoint, and \( t_{31} = 3.02, p = 0.005 \) for the recovery range. Regarding near positive fusional vergence, basketball players reached marginally significant higher fusional vergence values for the breakpoint and recovery \( t_{31} = 1.957, p = 0.059 \), and \( t_{31} = 1.941, p = 0.061 \), respectively. For the near point of convergence, closer breakpoints and recovery values were found for athletes \( t_{31} = -3.133, p = 0.004 \) and \( t_{31} = -2.615, p = 0.014 \), respectively. Finally, the accommodative response, facility of accommodation, and static near and far stereo acuity yielded no significant differences \( p > 0.05 \) between groups (Table 3).

Participants without a basketball background demonstrated significantly higher VDI than did the basketball players \( t_{31} = 3.282, p = 0.003 \) (Table 3; Fig. 1, which illustrates 2 participants in each experimental group). Basketball players showed better scores for eye–hand coordination \( t_{31} = 2.405, p = 0.022 \). On the other hand,
These types of action promote a constant implication of the vergence and accommodative system, as well as their mutual interactions.

4. Discussion

This investigation incorporates noteworthy findings in several categories: basketball players show a closer near point of convergence for breakpoint and recovery, a larger positive fusional vergence range, a better VDI index (e.g., lower scores), and higher scores in eye–hand coordination than for sedentary participants.

4.1. Accommodative and binocular function

In basketball, near-far visual changes are continual for ball interceptions, control, passing, and throwing the ball, as well as analyzing the positioning of teammates and opponents, among others. These types of action promote a constant implication of the vergence and accommodative system, which could produce a comparable effect to visual-therapy exercises. Exercises based on constant near-far changes in binocular viewing conditions are normally applied in optometry practice with the aim of normalizing the accommodative and vergence system, as well as their mutual interactions. Notably, we found that basketball players present a closer near point of convergence and a greater distance vergences range in athletes, respectively. On the contrary, no significant differences were found in the negative fusional vergences between groups in the current study. Similarly, Daum demonstrated that visual training in young adults with normal binocularity has a significant and prolonged effect on positive vergences, while fusional negative vergences resisted change. These substantial differences between the convergence and divergence systems seem to be explained because they are controlled by different neural centers. It is also well known that visual therapy gives the best results in the treatment of convergence insufficiency, acting on the reduced positive fusional vergences and receded near point of convergence.

No statistical differences were found for near static stereopsis, but a tendency to present different values between groups was appreciable (38.33 ± 20.72 for the basketball group vs. 86.33 ± 128.71 for the sedentary group). Along this line, Boden et al. found significant differences between baseball and softball players and non-ball players (25.5 ± 11.9 and 32.7 ± 2.8, respectively). Based on the information provided, the mean values for several visual characteristics in basketball players are presented in Table 3.

Table 3

| Ocular parameters evaluated according to the measurement method and group analyzed. Means ± SD were calculated from the mean values of each participant (n = 33, mean ± SD). |
|---|---|---|
| Binocular and accommodative function | Basketball players (n = 18) | Sedentary subjects (n = 15) | p |
| Accommodative response (D) | 0.50 ± 0.25 | 0.38 ± 0.24 | 0.155 |
| Accommodative facility (cpm) | 25.67 ± 3.46 | 27.60 ± 3.36 | 0.116 |

56.2 ± 60.7, respectively). Similarly, we found no differences for far static stereoaucuity, and these results agree with those of Paulus et al., who made comparisons for far static and dynamic stereopsis in professional and amateur soccer players vs. individuals without soccer background. The effect of specific eye exercises on stereoaucuity seemed to be modest and has a limited use in practical terms. Therefore, we can expect that systematic basketball practice does not involve substantial stereopsis improvements. Also, as indicated by Paulus et al., stereopsis tests are not sensitive enough to reveal differences between groups, and further developments in test methodology of stereopsis are needed.

The accommodative system is controlled by the autonomic nervous system, and the latter is more stable and efficient in athletes. Therefore, we might expect a better accommodative function in basketball players, but we detected no significant differences for the accommodative response between groups. We propose 2 possible explanations: firstly, the possible accommodation variations may be relatively smaller than MEM sensitivity (0.25 D), and more sensitive methods to test accommodative response would be necessary (e.g., open-field autorefractor or wavefront sensors). Secondly, and perhaps most influential, the ball and players are moving mainly at medium-long distances, which does not require great accommodative effort. Therefore, accommodation enhancements, which require high accommodative stimulation in visual training, are unlikely to be achieved only with regular basketball practice.

For its part, facility of accommodation in binocular conditions revealed no differences between groups. Little comparable work has been conducted, and only Jafarzadehpur et al. found significant differences when they compared professional and intermediate female volleyball players with beginners and non-players, but those differences disappeared when professionals were compared to intermediates. However, the method of measuring used in their work is not clear. Other authors, using a similar methodology to the one used in the present work, showed slightly better accommodative facility for a wide group of interceptive sports athletes than for non-athletes. That study involves not only basketball players but also a great variability of sport modalities (e.g., tennis, table tennis, baseball, volleyball, badminton), and the visual requirements for each discipline are substantially different.

4.2. Visual performance

No study available has investigated visual performance in sports using the VDI. The present study reports a better visual discrimination in athletes. It has importance because the perception of halos requires a longer time to recover after exposure to a high-luminance stimulus (e.g., glare). The glare phenomenon has great importance in basketball, and players are constantly exposed to glare due to illumination conditions in basketball courts. The differences found between basketball players and sedentary individuals could be explained from the perspective that abilities involved during the game are inherently developed while playing the sport (e.g., higher tolerance), as occurs with the better selective attention demonstrated in international basketball players.

4.3. Visual-information processing

Our results confirm that basketball players show better eye–hand coordination than do individuals without basketball background. This study agrees with Kioumourtzoglou et al. who found a similar result in members of the Greek national team, arguing different perceptual strategies from experts to novices in relevant and irrelevant cues. In relation to visual–reaction time, previous studies have indicated that players from different disciplines (e.g., water polo or soccer) had faster visual–reaction compared with novices or non-athletes, but no differences were found for basketball players, as in this study. It may demonstrate that the nature of each sport strongly influences the development of visual skills with constant practice. Along the same line, other authors have stated that athletes have a similar speed of response as non-athletes but differ in the ability to detect pertinent cues associated with the higher level of expertise in sport.

4.4. A plausible explanation

Previous works have supported the contention that differences between an athlete and a sedentary participant arise from visual-information processing and interpretation rather than from basic visual skills. This study supports the hypothesis that athletes could present a combination of better basic visual function, as well as perceptual and cognitive factors than do non-athletes, as explained by several authors. However, this study does not elucidate whether there is an innate visual superiority in athletes or whether those superior skills are achieved due to the constant sport practice. In addition, the different visual demands required in each sport discipline could influence the development of visual, perceptual, and cognitive skills. The vast majority of studies have reported that better visual skills would play a positive role in sports performance. This advantage on visuo-oculomotor abilities can lead to faster and better interceptive skills, motor response, and decision making. For example, a recent study indicates that visual tracking speed is related to a greater number of assists and steals and lower turnovers in NBA players. Moreover, considering that our athletes never received specific visual training implies that basketball training in itself might be responsible for the differences in some visual capacities between basketball players and non-players, as explained by Alves et al. for professional soccer players.

4.5. Implications for future research

Due to the great number of sport disciplines, further studies should be performed to analyze the differences for the visual system. We would like to encourage researchers to investigate whether visual training could be transferred to sport performance in the field environment. Some work is currently being performed in this area, but more data are needed. It would be useful to explore the possible visual function improvements with systematic sport practice in persons who have impaired...
Visual characteristics in basketball players

visual function (e.g., convergence insufficiency, vergence fusional dysfunction, etc.), as it has been demonstrated on different health conditions.46

5. Conclusion

This article presents evidence of the differences between basketball players and sedentary individuals with respect to some skills of their visual function, performance, and processing. Both groups have proved to have different sport backgrounds as reflected by the HRV parameters and as indicated in the demographic questionnaire. In comparison to control group, basketball players clearly present benefits in near point of convergence, positive fusional vergences, halo discriminability, and eye-hand coordination. Our results suggest that systematic basketball practice might be responsible for the development of certain visual abilities.

Acknowledgments

The authors thank to Ernesto Suarez and David Nesbitt for translating the text into English. We also would like to acknowledge all the participants who selflessly participated in this study. This study was funded in part by a Spanish Ministry of Economy and Competitiveness grant (DEP2013-48211-R).

Authors’ contribution

JV conceived of the study, participated in data collection, performed the statistical analysis, and drafted the manuscript; RJ conceived of the study, coordinated, and drafted the manuscript; DC coordinated and helped to draft the manuscript; BR performed the statistical analysis, and drafted the manuscript; JAG participated in data collection and drafted the manuscript; JAG coordinated and drafted the manuscript. All authors have read and approved the final version of the manuscript, and agree with the order of presentation of the authors.

Competing interests

The authors declare that they have no competing interests.
